Abstract

We describe improved modelling of the emission by dust in a toroidal-like structure heated by a central illuminating source within active galactic nuclei (AGNs). We have chosen a simple but realistic torus geometry, a flared disc, and a dust grain distribution function including a full range of grain sizes. The optical depth within the torus is computed in detail taking into account the different sublimation temperatures of the silicate and graphite grains, which solves previously reported inconsistencies in the silicate emission feature in type 1 AGNs. We exploit this model to study the spectral energy distributions (SEDs) of 58 extragalactic (both type 1 and type 2) sources using archival optical and infrared data. We find that both AGN and starburst contributions are often required to reproduce the observed SEDs, although in a few cases they are very well fitted by a pure AGN component. The AGN contribution to the far-infrared luminosity is found to be higher in type 1 sources, with all the type 2 requiring a substantial contribution from a circumnuclear starburst. Our results appear in agreement with the AGN unified scheme, because the distributions of key parameters of the torus models turn out to be compatible for type 1 and type 2 AGNs. Further support

to the unification concept comes from comparison with medium–resolution infrared spectra of type 1 AGNs by the *Spitzer* observatory, showing evidence for a moderate silicate emission around 10 μ m, which our code reproduces. From our analysis we infer accretion flows in the inner nucleus of local AGNs characterized by high equatorial optical depths ($A_V \approx 100$), moderate sizes ($R_{max} < 100$ pc) and very high covering factors ($f \approx 80$ per cent) on average.

1 Introduction

The idea that the quasar infrared (IR) spectral energy distribution (SED) could be dominated by thermal emission from dust has already been proposed by Neugebauer et al. (1979), who noted an excess at ~3.5 μ m with respect to the power-law emission that was known to dominate the ultraviolet (UV) and optical spectrum. Barvainis (1987) was the first to demonstrate that it was possible to describe this emission by means of thermal radiation from dust heated by the primary optical/UV continuum known to dominate type 1 active galactic nucleus (AGN) SEDs. He considered an optically thick, either smooth or a clumpy dust distribution within a non-spherical geometry. Such a model could naturally account for the observed 3- μ m bump, which was attributed to graphite grains with temperatures close to their sublimation limit. The broadness of the IR SED, which could not be reproduced by means of a single-temperature blackbody, was explained in terms of multiple temperature components of dust.

More quantitative models have been developed since then, accounting for different features and using different computational approaches for solving the radiative transfer equation. Pier & Krolik (1992) suggested an emission model from an annular ring of dust. Assuming a common extinction curve for all of the grains, a distribution function of grain composition and sizes as given in Mathis, Rumpl & Nordsieck (1977) and not accounting for light scattering, they solved the radiative transfer problem with the Böhm—Vitense method described in Mihalas (1978). Based on this model, they explored the main properties of IR emission in AGNs, such as the width of the SED and the wavelength of peak emission, IR colours and the presence and/or absence of the 9.7- μ m silicate feature.

Granato & Danese (1994) solved the radiative transfer equation by means of the Λ -iteration method (see Section 2.6 for more details), adopting the Rowan-Robinson (1992) model for interstellar dust, based on both graphite and silicate grains, and taking into account radiation scattering. Their adopted geometry was the so-called 'flared disc', with dust grain density that was allowed to vary both along the radial and the vertical coordinates.

Stenholm (1994) studied a configuration given by an optically thick silicate disc, finding no need for silicate grain depletion or non-standard dust composition in order to weaken the strength of the 9.7- μ m feature, which turned out to be weak in most of his models with optical depth larger than 1. Furthermore, he found that, in contrast with Pier & Krolik (1992), scattering is not negligible and does affect the shape of the near-IR emission in those models where optical depth is high.

Efstathiou & Rowan–Robinson (1995) analysed three different geometrical configurations for the torus (a flared and a tapered disc and an anisotropic sphere) and found that a tapered disc (i.e. a disc whose height increases along with distance from the centre but flattens at a constant height in the outer parts) with an opening angle of 45° was the most successful representation of what was observed. They followed a ray–tracing numerical method, with the same dust mixture as in Rowan–Robinson (1992). The sublimation temperature was assumed to be 1000 K for all grains, while the distances from the central source where this temperature is reached were assumed to be dependent on the grain size. Along the same lines, Manske, Henning & Men'shchikov (1998) modelled the dusty torus as a flared disc in which both graphite and silicate were taken to sublimate at a temperature of 1500 K. In their analysis they concluded that flared tori, dust composed of silicate and graphite grains and a power-law density distribution failed to explain the observed featureless AGN spectra.

In parallel, Nenkova, Ivezic & Elitzur (2002) developed a torus model in which dust was distributed in clumps. They solved the radiative transfer for each clump by means of the radiative code DUSTY (Nenkova, Ivezic & Elitzur 1999) and then computed the final emission as the sum of clump emission calculated using a ray-tracing approach.

At variance with Efstathiou & Rowan-Robinson (1995), van Bemmel & Dullemond (2003) claim that the obscuring torus could not be flat (tapered, for example), and should rather be conical or flaring. Their more reliable models predicted constant density over the whole torus and a quite large value for the inner radius (~10 pc), which they found necessary in order to fit observed colours. They also tried to modify the power-law distribution function for grain sizes with respect to that given by Mathis et al. (1977), in order to attenuate the strength of the $10-\mu m$ silicate feature and they recently concluded that there was no need for a clumpy dust distribution (Dullemond & van Bemmel 2005).

In this paper we try to combine most of the successful features of the previous works to build an improved model explaining IR emission in AGNs. The paper is organized as follows. In Section 2 we present the physical and computational details of the model. In Section 3 we discuss the contribution of each of the model parameters in the produced SEDs. In Section 4 we explain the observed SEDs of a series of objects taken from the literature using various realizations of the torus model in combination with starburst templates. Finally, in Section 5 we discuss our results and conclusions.

2 Model Description

2.1 Torus geometry and grain sublimation

We use a simple but realistic geometry for the spatial distribution of dust: the flared disc (Efstathiou & Rowan–Robinson 1995; Manske et al. 1998; van Bemmel & Dullemond 2003), which can be represented as two concentric spheres, delimiting respectively the inner and outer torus radii, having the polar cones removed.

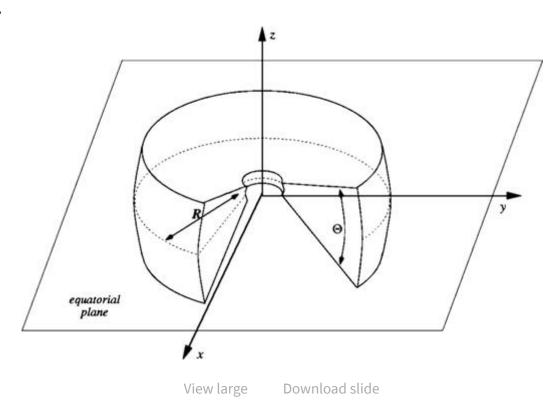

The size of the torus is defined by the outer radius R_{max} — the inner radius being defined by the sublimation temperature of dust grains under the influence of the strong nuclear radiation field — and by the angular opening angle Θ of the torus itself (see Fig. 1). Considering a typical graphite grain with radius a_{G} = 0.05 μ m and using the thermal equilibrium equation (see equation 7), Barvainis (1987) derives the following formula to compute the distance at which this grain reaches the sublimation temperature:

$$R_{\min} \simeq 1.3 \sqrt{L_{46}^{\text{AGN}}} T_{1500}^{-2.8}$$
 (pc). (1)

Here, L^{AGN}_{46} is the bolometric UV/optical luminosity emitted by the central source, expressed in units of 10^{46} erg s⁻¹ and T_{1500} is the sublimation temperature of the dust grain given in units of 1500 K. Note that this relation depends on both the grain dimension and species but we here assume as a common minimum radius the average one. We account for the different sublimation temperature of silicate grains, however, yielding a minimum radius that can be up to three times larger than that for graphite. Furthermore, the presence of the dust layer composed by graphite grains, which

attenuates the X-ray and UV emission, is taken into account when computing the silicate minimum radius.

Figure 1.

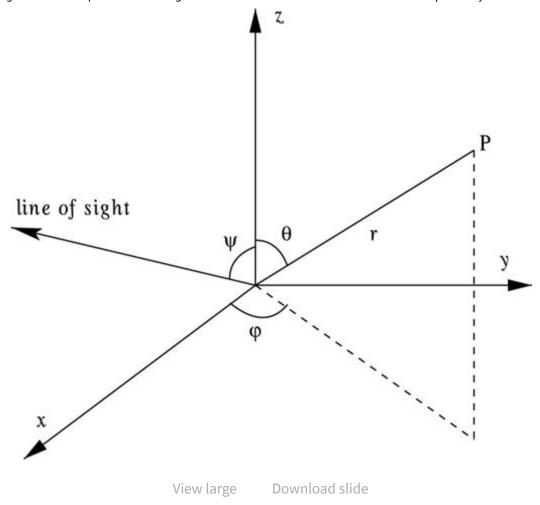

Shape of the toroidal dust distribution in our model. In this figure R is the ratio of the external to internal radius and Θ is the full-opening angle of the torus.

2.2 Definition of the geometrical grid

We define a geometrical grid with reference to a polar coordinate system (r, θ, ϕ) , as shown in Fig. 2, by dividing the torus into volume elements. We then compute all the quantities of interest within a given volume element as if all dust properties were those of the centre. Because the temperature gradient is higher in the inner parts, we used a logarithmic-spaced division for the radial coordinate, in order to better sample the properties of the emission in the innermost regions.

Figure 2.

The geometrical grid is defined with respect to a spherical coordinates system. The equatorial plane of the torus lies in the xy plane, so that when the view angle Ψ = 90° the geometry reproduces a type 2 objects, while Ψ = 0° would correspond to the type 1 view, according to the unified model.

The grid has a constant number of subdivisions in the azimuthal coordinate (ϕ) that is fixed to 36, while the equatorial distance coordinate is divided into 12, 14 and 16 parts for models with 60°, 100° and 140° of torus amplitude, respectively. The radial coordinate is divided into 40, 80 and 120 parts for $R_{\text{max}}/R_{\text{min}}$ = 30, 100 and 300, respectively. The wavelength values at which the spectrum is computed consist in a grid equally spaced in logarithm with 120 points in the range from 10⁻³ to 10³µm.

Neither the computation of the emitted radiation from each grain species in each volume element within the torus, nor the computation of the optical depth between all torus cells is particularly CPU time-consuming. However, for a typical ~15 000 element grid (see Section 3.1) this computation must be repeated ~15 000² times, if we want to evaluate the contribution to the radiation field in each element from all others in the torus. It is therefore essential to exploit all the symmetries of the adopted geometry, identifying groups of volume elements whose properties are identical all over the torus grid. For instance, all volume

elements at any given ϕ have exactly the same dust density, temperature and emission conditions. It is sufficient to compute these quantities just for these elements, which we refer to as sample elements.

Furthermore, when computing the incoming radiation on a given sample element, the problem is symmetric with respect to the *xz* plane, so it is possible to compute incoming radiation from just one side of the torus.

2.3 Dust properties

The main dust components are silicate and graphite grains, in almost equal percentages. The former are responsible for the observed absorption feature at ~9.7 μ m in type 2 objects, while the latter are responsible for the rapid decline of the emission at wavelength shortwards of a few μ m, corresponding to a blackbody emission of about 1500 K, the sublimation temperature for these particular grains.

Most models in the literature make use of a small number of grain categories at different sizes (e.g. Granato & Danese 1994; Efstathiou & Rowan–Robinson 1995). Following an approach similar to that of van Bemmel & Dullemond (2003), we decided to adopt a more complete distribution using, for each of the two species, scattering and absorption coefficients given by Laor & Draine (1993) for different grains sizes from 0.005 to 0.25 μ m and from 0.025 to 0.25 μ m for graphite and silicate, respectively.

As for the distribution function for the grain sizes *a* we adopted the Mathis—Rumpl—Nordsieck (MRN) distribution (see Mathis et al. 1977)

(2)

where dN(a) is the number of grains with radius between a and a+d a normalized to the number of hydrogen atoms. As for the exponent q, the value of the standard galactic extinction curve (q=-3.5; Mathis et al. 1977) has been adopted, so that the extinction curve that characterizes our model is similar to the galactic one. The constant A_i gives the normalization with respect to hydrogen abundance, and it is taken to be -25.16 for graphite and -25.11 for silicates (Draine & Lee 1984).

2.4 Density law throughout the torus

We adopted a law for the gas density within the torus allowing for a density gradient along the radial and the polar distance (θ) coordinates:

$$\rho(r,\theta) = \alpha r^{\beta} e^{-\gamma |\cos(\theta)|}.$$
(3)

The normalization constant α here is a linear function of the equatorial optical depth (see Section 2.7). The latter is used in the following instead of the α parameter.

2.5 Spectral intensity of the central power source

We assume that the torus is illuminated by a central point-like energy source with isotropic emission. We define its spectrum in the wavelength range $0.001-20~\mu m$ (corresponding to the frequency range $\sim 3 \times 10^{17}$ to $\sim 1.5 \times 10^{13}$ Hz) and describe it as a composition of power laws with variable indices. The values that we have adopted are the same as in Granato & Danese (1994) or Nenkova et al. (2002), namely

$$\lambda L(\lambda) = \begin{cases} L_0 \lambda^{1.2} & (\text{erg s}^{-1}) & \text{if } 0.001 < \lambda < 0.03 & (\mu \text{m}) \\ L_0 \lambda^0 & (\text{erg s}^{-1}) & \text{if } 0.03 < \lambda < 0.125 & (\mu \text{m}) \\ L_0 \lambda^{-0.5} & (\text{erg s}^{-1}) & \text{if } 0.125 < \lambda < 20.0 & (\mu \text{m}) \end{cases}$$

$$(4)$$

where L_0 sets the bolometric luminosity normalization constant.

2.6 Solution of the radiative transfer equation

The radiation emitted by the above–described physical configuration is given by the sum of the primary source located in the torus centre and a secondary contribution given by thermal and scattering dust emission. Therefore, dust plays a double role, first absorbing the radiant energy emitted by the primary source, partially or totally obscuring it, then re–emitting it at longer wavelengths, typically in the spectral range 1–1000 μ m. A complication arises from the fact that dust can be optically thick to its own radiation. This requires the solution of the radiative transfer equation (equation 5). In particular, the presence of a dust scattering component makes this equation not solvable analytically: the source function is not known a priori, depending on the solution I_{ν} itself.

The thermal and scattered components of dust radiation are described by the absorption (α_v) and the scattering (σ_v) coefficients respectively, so that the radiative

transfer equation is written as

$$\frac{\mathrm{d}I_{\nu}}{\mathrm{d}s} = -\left(\alpha_{\nu} + \sigma_{\nu}\right)\left(I_{\nu} - S_{\nu}\right),\tag{5}$$

where S_V is the source function, which can also be written as (see Rybicki & Lightman 1979)

$$S_{\nu} = \frac{\alpha_{\nu} B_{\nu} + \sigma_{\nu} J_{\nu}}{\alpha_{\nu} + \sigma_{\nu}},\tag{6}$$

i.e. a weighted average of the two separate source functions.

We solved the transfer equation numerically adopting the Λ -iteration method. A lower limit for the incident radiation is estimated assuming that the only source of radiation (and hence of dust heating) is the central, non-thermal, source. The equilibrium temperature (and hence thermal emission) of the grains of each species in each sample element is found by solving the thermal equilibrium equation

$$\int_{\lambda_m}^{\lambda_M} Q_{abs}(\lambda) J^{ik}(\lambda) d\lambda - \int_{\lambda_m}^{\lambda_M} Q_{em}(\lambda) B(\lambda, T_{ik}) d\lambda = 0,$$
(7)

where the equation is written for a given species of grain and $B(\lambda, T_{ik})$ is the blackbody emission. T_{ik} is the temperature of a given grain within the ikth sample element, J^{ik} represents the incoming specific intensity on the volume element, written, for the first iteration, as

$$J^{ik}(\lambda) = I_{AGN}(ik, \lambda) = \frac{1}{4\pi} \frac{L(\lambda)}{4\pi r_{ik}^2} \exp[-\tau_{ik}(\lambda)].$$
(8)

Here $\tau_{ik}(\lambda)$ is the optical depth between the central source and the *ik*th sample element and r_{ik} is its distance.

At the second iteration, the new incoming radiant flux on each grain of a given geometrical element *ik* that will enter in the equation (7) of the thermal equilibrium is

8/23/2018 Revisiting the infrared spectra of active galactic nuclei with a new torus emission model | Monthly Notices of the Royal Astron...

$$J^{ik}(\lambda) = I_{\text{AGN}}^{ik}(\lambda) + \frac{1}{4\pi} \sum_{e=1}^{N-1} \times \frac{1}{4\pi r_{ik,e}^2} \left\{ \sum_{id}^{Ndust} \left[4\pi\pi a_{id}^2 Q_{id}^{\text{em}}(\lambda) B(\lambda, T_{e,id}) + 4\pi\pi a_{id}^2 Q_{id}^{\text{sca}}(\lambda) J_{tot}^e(\lambda) \right] e^{-\tau_{ik,e}(\lambda)} \right\}$$

$$(9)$$

where e indicates the generic volume element and N is their total number. $J^e_{tot}(\lambda)$ is the total specific intensity hitting the e-element and coming from both the AGN and the dust from the rest of the torus (scattering plus thermal) as computed from the previous step.

These calculations are iteratively repeated until the difference in the temperature value between two steps falls below one Kelvin for each grain species in each volume element. If such small variations do not have a big influence on the final result when dealing with relatively low-density environments, it is important to achieve a good convergence when dealing with high optical depth tori, to avoid losses of energy due to the numerical method adopted.

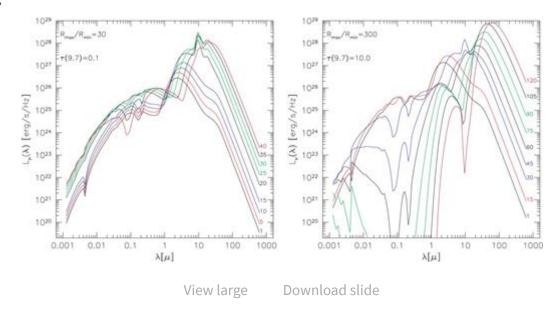

The conservation of energy is always verified within 1 per cent for typical solutions and up to 10 per cent for solutions with very high optical depth and non-constant dust density. These discrepancies are due to some approximations in the maximum temperature of the grains, but do not affect any of our conclusions.

In models with high dust densities where thermal emission strongly contributes to the self-heating of the dust, the smaller grains can reach and even slightly exceed the sublimation temperature. In order to avoid further recalculation of the optical depth and density profiles — which would result in a large increase of the computation time — temperatures that are too high are set equal to the sublimation value. If this also occurs for the 0.05- μ m grains, then the inner radius is moved further out with respect to the value computed by means of equation (1).

Various model solutions are reported in Fig. 3, which shows dust emission from elements at different distances from the central source. The model solution on the left is built with a total opening angle of the torus of 140°, a ratio $R_{\rm max}/R_{\rm min}$ = 30 and a constant density profile with equatorial optical depth $\tau_{\rm eq}$ (9.7) = 0.1. The minimum radius turns out to be 1.30 pc for graphite and 6.27 pc for silicate grains. The contribution to emission from the silicate grains, which is easily recognizable from the feature in emission at 9.7 μ m, only appears after the

element number 15. The scattering component of radiation is clearly visible shortwards of $\lambda \sim 1\,\mu m.$

Figure 3.

Emission spectra by torus elements at increasing radial coordinates for dust torus distributions illuminated by a nuclear source of $L^{AGN} = 10^{46}$ erg s⁻¹. Two extreme cases are shown. In the left panel, a model with equatorial optical depth $\tau(9.7) = 0.1$ and an outer-to-inner radii ratio of 30 is shown. The closest element to the central source is labelled 1, the most distant 40 (the different lines correspond to physical locations of 1.36, 1.91, 2.92, 4.50, 6.8, 10.4, 16.0, 24.4 and 37.4 pc). In the right panel, the equatorial optical depth is taken to be $\tau(9.7) = 10.0$ and the outer-to-inner ratio is 300.

The model shown on the right has the same opening angle for the torus, an outer-to-inner ratio of 300, constant density profile and τ_{eq} (9.7) = 10.0. In this case, the minimum radius is the same (1.3 pc) for graphite, but it is lower for silicate grains (3.94 pc) whose emission appears after the element number 30 over a total of 120 radial subdivisions.

2.7 Details of the computation of dust density and optical depth

The model needs as a starting point the value of the equatorial optical depth at a given reference wavelength. Starting from this input condition we calculate the gas and dust densities and the number of the different dust grains within each sample element. With reference to equation (3), providing the spatial variation of density through the β and γ parameters, the problem is to find the α value yielding an equatorial optical depth τ_{eq} (λ_{ref}). The expression for the latter is

8/23/2018 Revisiting the infrared spectra of active galactic nuclei with a new torus emission model | Monthly Notices of the Royal Astron...

$$\tau_{\text{eq}}(\lambda_{\text{ref}}) = \int_{R_{\text{min}}}^{R_{\text{max}}} \left\{ \sum_{id=1}^{Ndust} \left[Q_{id}^{A}(\lambda_{\text{ref}}) + Q_{id}^{S}(\lambda_{\text{ref}}) \right] \times a_{id}^{2} \pi N d_{id} \rho_{H}(r, \theta) \, dr \right\}$$
(10)

where Nd_{id} is the numeric density of the idth grain, normalized to that of hydrogen. Taking this into account and the difference in the sublimation temperatures of graphite and silicate and the discontinuity in the chemical composition of dust along the radial coordinate, the density is a step function that can be written as

$$\rho_{id}^{\text{dust}}(r,\theta) = \begin{cases} 0 & r < R_{\text{Sil}} \\ \rho_{id}^{\text{dust}}(r,\theta) & r > R_{\text{Sil}} \end{cases}$$
(11)

where the indices id refer only to the silicate component. An analogous condition applies to the graphite grain distribution and their corresponding id indices. Substituting ρ from equation (3) into equation (10) and solving for α , we obtain the correct value of density and number of dust grains at each point of the grid.

The most general expression for the optical depth between any two points $P_1(r_1, \theta_1, \phi_1)$ and $P_2(r_2, \theta_2, \phi_2)$, located within the torus is

$$\tau_{1,2}(\lambda) = \int_{r_1}^{r_2} \int_{\theta_1}^{\theta_2} \int_{\varphi_1}^{\varphi_2} \sum_{id=1}^{Ndust} \left[Q_{id}^A(\lambda) + Q_{id}^S(\lambda) \right] \\
\times \pi a_{id}^2 \, N d_{id} \rho_{id}^{\text{dust}}(r,\theta) \, d\varphi \, d\theta \, dr. \tag{12}$$

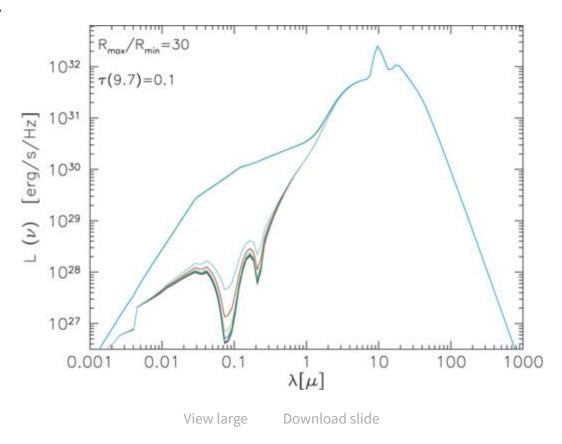

The optical depth is calculated as the path-integral of the density function $f(r, \theta, \phi) = \alpha r^{\beta}$ $e^{-\gamma|\cos(\theta)|}$ along the straight line between the two points. Considering the conditions (11) in equation (12) automatically accounts for the fact that there are inner regions free of silicates due to their lower sublimation temperature and regions completely dust-free.

2.8 Calculation of the emitted spectrum

Adding the emission from all torus elements to that of the central source, attenuated by the correct value of optical depth when needed, yields the total emitted spectrum. Here it is computed for 10 different inclination values of line of sight, spanning from 0° to 90° with respect to the equatorial plane.

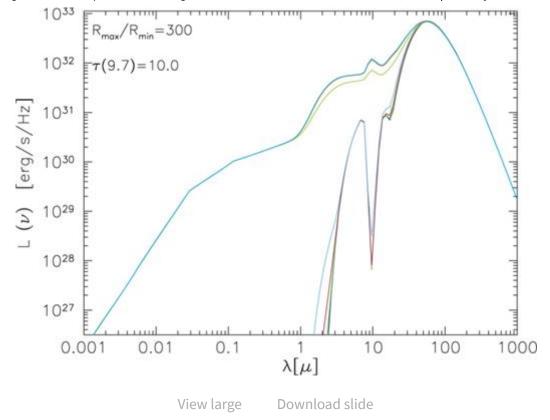

In Figs 4 and 5 we show two emission models with different lines of sight and different physical and geometrical parameters. The first model is meant to represent a geometry in which the amplitude of the torus is 140°, the ratio between external and internal radii is $R_{\text{max}}/R_{\text{min}}$ = 30, the density is constant and the optical depth is $\tau(9.7)$ = 0.1. Such a configuration is obtained with a hydrogen column density of 9.0×10^{21} cm² and corresponds to an optical extinction of A_V = 2.3. Note that the shape of the SED remains quite constant with varying angle, as long as the central source is seen directly. A similar behaviour is found when both the optical depth and the torus size increase. The emission pattern of Fig. 5 has a radial ratio of 300 and the equatorial optical is $\tau(9.7)$ = 10.0.

Figure 4.

Emission spectra obtained for 10 different line-of-sight inclinations from 0° to 90° at regular steps of 10°. Here the torus amplitude angle is 140°, the ratio between the outer and inner radii is $R_{\text{max}}/R_{\text{min}}$ = 30, the density is constant and the equatorial optical depth is $\tau(9.7)$ = 0.1.

Figure 5.

Emission spectra as a function of wavelength for 10 different lines of sight (see also Fig. 4) for a geometrical configuration with $\tau(9.7) = 10.0$, $R_{\text{max}}/R_{\text{min}} = 300$, torus opening angle $\Theta = 140^{\circ}$ and constant density profile.

3 Model Realizations

We have computed a grid of models by varying the different parameters. Some of their main features and a rough comparison with other models in literature are presented here.

3.1 Grid of model solutions

We obtained a set of models spanning the widest range of physical and geometrical characteristics of dusty tori discussed in the literature. The models have varying radial ratios $R_{\text{max}}/R_{\text{min}}=30$, 100 and 300, corresponding to radial sizes from about 40 to about 400 pc (for an accretion luminosity of 10^{46} erg s⁻¹), while the torus full opening angles were taken to be 60° , 100° and 140° , corresponding to sizes of the torus between a minimum of ~20 to a maximum of ~370 pc. The equatorial optical depth was always measured at λ = 9.7 μ m and the models have been computed at values of τ (9.7) = 0.1, 0.3, 0.6, 1.0, 2.0, 3.0, 6.0 and 10.0, translating into values of absorption in the *V* band from a few to a few hundred magnitudes, depending also on the $R_{\text{max}}/R_{\text{min}}$ ratio. The parameters used to define the law for the spatial behaviour of density were β = 0, τ - 0.5 and τ -1.0 and τ = 0 and τ 6 (see equation 3 for the

definitions). In order to have a full exploration of the parameter space, we also considered models with density increasing towards the outer parts of the torus, obtained by setting β = 0.5. In Table 1 we summarize the main features of the model grid.

Table 1.

Parameter	Adopted values
$R_{\rm max}/R_{\rm min}$	30, 100, 300
$\tau_{\rm eq}$ (9.7 μ m)	0.1, 0.3, 0.6, 1.0, 2.0, 3.0, 6.0, 10.0
β	0.5, 0.0, -0.5, -1.0
γ	0.0, 6.0
Θ	60°, 100°, 140°

The parameters of the models of the grid.

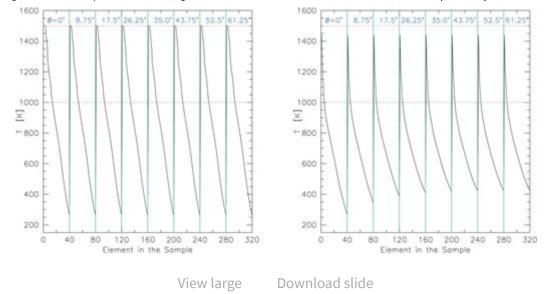

3.2 Main features of the models

3.2.1 Distribution of grain temperatures

One of the most evident features of the AGN IR emission is the presence of multiple temperature components. Especially when viewed face-on, the whole range of temperatures can be seen, from the innermost part — where grains are close to the sublimation limit — to the outer shells where the dust is colder, only heated by reprocessed IR radiation.

For models in which the spatial profile of density is kept constant with respect to the altitude angle θ , the temperature is assumed to vary only along the radial coordinate. Models with non-constant density profiles can show a temperature gradient also with respect to the altitude coordinate. In Fig. 6 we show the trend of the dust equilibrium temperature as a function of the coordinates of the sample element. Two extreme cases are shown: a model with $\tau(9.7) = 0.1$, $R_{\text{max}}/R_{\text{min}} = 30$ and a constant density, and a model with the same parameters but a density profile varying as $r^{-1.0}$ e^{$-6|\cos(\theta)|$} (in both cases a graphite grain with radius of $0.01~\mu\text{m}$ is considered).

Figure 6.

Temperature profiles of graphite grains with a radius of 0.01 μ m as a function of the torus element. Each vertical blocks spans the radial distance of the torus and corresponds to a different polar angle. In the left panel, a model with constant density profile, τ = 0.1 and radii ratio of 30 is shown. In this case, the only temperature gradient present is that with respect to the radius. The right panel shows a model with the same characteristics but also with a non-constant density profile (β =-1.0 and γ = 6). The horizontal lines represent the values of sublimation temperature assumed for graphite (1500 K) and for silicate (1000 K) grains, respectively.

In the case of a constant dust density distribution, the temperature profiles drop roughly linearly with the distance from the central source. A non-constant density profile, in our case peaking in the inner part of the torus (close to the central source and to the equatorial plane), brings some differences. First of all, the decrease of dust density with increasing altitude on the equatorial plane results in lower values of the optical depth of the elements at a lower θ coordinate. The temperature in the most distant volume elements will then increase with increasing altitude with respect to the equatorial plane. Furthermore, because the dust density peaks in the innermost regions, the temperature gradient will be higher for those volume elements that are closer to the inner edge of the torus. Moreover, the high-density (and hence high optical depth) values that are found close to the inner radius are responsible for not always reaching the sublimation temperature; in such configurations the central source undergoes a high attenuation in the first layers of dust.

3.2.2 Dependence on the viewing angle

As expected for a geometry with no spherical symmetry, the emission is highly anisotropic especially when the lines of sight that cross the torus and those that see the AGN directly are considered (see Figs 4 and 5). This feature is further highlighted if we consider a pattern in which the density is not constant along the altitude angle θ .

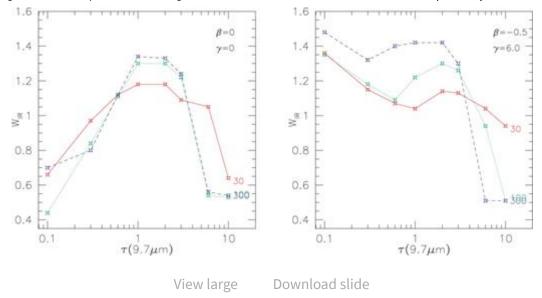

Figs 4 and 5 show that the SED remains quite constant even with varying line-of-sight angle, until the latter intersects the dust-free zone, i.e. at $\Psi < 90^{\circ}-\Theta/2$. The only part of the emission that changes is that shortwards of 1 μ m for low optical depth models, where the emission of the non-thermal central source is directly seen in the type 1 scheme configuration. In high optical depth systems, this behaviour is maintained, but the drastic difference between type 2 and type 1 concerns the emission shortwards of 30 μ m.

If a non-constant density pattern is assumed, the change is smoother because the emission from the central source becomes more visible as the torus is seen at decreasing polar angles, where the density is assumed to be lower with respect to the equatorial plane. Notice that with such density profiles and in those models with low optical depth values, the direct view of the central source is achieved even when $\Psi > 90^{\circ} - \Theta/2$ because the optical depth at higher altitudes becomes small enough. Then a substantial contribution of the accretion disc emission can be seen even through the dust cone. Configurations with a decreasing number of dust grains with increasing altitude on the equatorial plane can be considered to mimic the tapered torus geometry analysed by Efstathiou & Rowan–Robinson (1995), because, at least for low values of the equatorial optical depth, i.e. $\tau(9.7) < 1.0$, the bulk of emission comes from those volume elements that are closer to the equatorial plane. The other elements of the geometrical grid will in fact provide a smaller contribution to the total emission, as they will contain a smaller number of grains.

3.2.3 Width of infrared spectrum

One of the most important features of a dusty torus model is the capability of reproducing the observed width of the IR spectrum due to multitemperature emission. Both Pier & Krolik (1992) and Granato & Danese (1994) use for its measure the logarithmic wavelength interval in which the power λF_{λ} emitted in the IR is more than one-third of the peak value (W_{IR}). When measured on a blackbody this parameter has a value of ~0.7 while, for example, in the observed spectra used by Granato & Danese (1994) its value is always larger than 1.3. In Fig. 7 we report on the trend of the bump width as a function of optical depth for different torus sizes, as viewed along the torus equatorial plane. This parameter depends both on the optical depth value and on the torus size; increasing the values of the optical depth will tend to generally shrink the bump because the inner, hotter, parts will become less visible. At rising values of the radii ratio, the bump will tend to broaden, because larger radii imply higher amounts of colder dust.

Figure 7.

The trend of the IR bump width is shown as a function of the optical depth and for various radii ratios. The parameter W_{IR} is defined as the logarithmic interval in wavelength, where the power emitted is more than one-third of the maximum. In the left panel, models with homogeneous density distributions are shown, while in the right panel a model with density parameters $\gamma = 6.0$ and $\beta = -0.5$ is plotted.

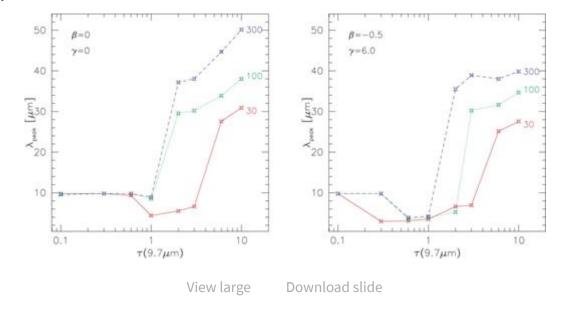

There are a few considerations to be made on the interpretation of the $W_{\rm IR}$ trend in Fig. 7. The maximum of emission for low values of optical depth falls right on top of the silicate feature, which in these cases can display a very intense emission. This will in turn give a low value for the bump width as defined by Pier & Krolik (1992). Furthermore, very high values of optical depth will cause the silicate feature to appear in strong absorption especially at equatorial optical depth higher than 6, resulting, again, in a low width for the IR bump.

A density profile peaking towards the innermost regions of the torus is less affected by this behaviour. This is mainly due to the fact that in the latter case the silicate feature is less prominent both in emission and in absorption, compared to a constant dust distribution configuration.

3.2.4 Peak of the infrared emission

Another important parameter that can be used to characterize a model solution is λ_{max} , the wavelength at which the IR emission — expressed as $\lambda F(\lambda)$ — peaks. In Fig. 8 this parameter is shown against the optical depth and for the three torus sizes for which the model has been computed. Only type 2 (equatorial view) emission is shown here. The peak wavelength ranges from 9.7 μ m, corresponding to the presence of a strong silicate emission in models with low optical depth, to about 60 μ m obtained in the models with the largest outer radii and optical depth values.

Figure 8.

Dependence of the wavelength of the peak IR emission (expressed in λF_{λ}) on the optical depth and torus size for a constant (left panel) and a non-constant (right panel) density distribution in the torus, calculated for a type 2 viewing angle. The constant value of ~10 μ m for small values of optical depth is due to the presence of the intense 9.7- μ m silicate emission dominating the spectrum. Here the dependences on the optical depth and on the torus size are comparable. No significant differences are found for the non-constant density model.

A non-constant dust density profile results in a hotter emission, with the emission peaking at smaller wavelengths. This occurs because lower densities — and hence lower optical depths — on the outer regions of the torus make the inner, hotter, regions more visible to the observer, increasing this way the average observed temperature.

3.2.5 9.7-µm silicate feature

The presence of the absorption feature at 9.7 μm in the spectra of Seyfert 2 galaxies has been used in the literature as a proof for the presence of silicate grains. At the same time, IR observations often showed rather featureless spectra for Seyfert 1 galaxies, which brought into question the reliability of the unified model; the characteristics of the silicate emission at this wavelength have become a crucial test of the validity of models. Nenkova et al. (2002) suggested that a clumpy distribution of dust may provide an explanation for the lack of the silicate feature in type 1 sources, while Dullemond & van Bemmel (2005) claim that the same result can be achieved in smooth tori. The depth of the same feature in type 2 sources, however, is shallower in clumpy tori.

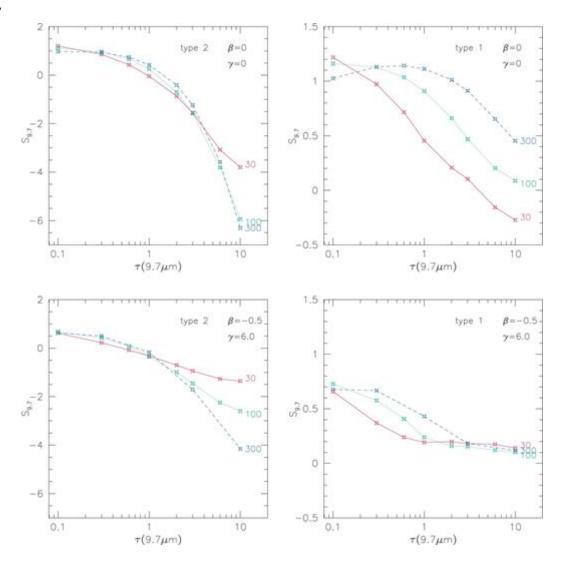

Only very recently, Siebenmorgen et al. (2005) and Hao et al. (2005) have found clear observational evidence for the presence of the 9.7- μ m silicate emission feature in type 1 quasars from spectral observations by the *Spitzer* space telescope.

Following Pier & Krolik (1992) and Granato & Danese (1994), we measured the amplitude of this feature by means of the dimensionless parameter $S_{9.7}$, defined as the natural logarithm of the ratio between the actual flux emitted at 9.7 μ m and the flux value at the same wavelength interpolated between 6.8 and 13.9 μ m:

$$S_{9.7} = \ln \left[\frac{F(9.7)}{F_C(9.7)} \right].$$
 (13)

In Fig. 9 we report on the variation of the parameter $S_{9.7}$ as a function of the external to internal radial ratios and of the optical depth for type 2 (left panel) and type 1 lines of sight (right panel). A homogeneous distribution of dust is assumed for models in the upper panels while in the lower panels the behaviour of non-constant density models is shown.

Figure 9.

View large Download slide

The variation of the 9.7- μ m feature intensity $S_{9.7}$ as a function of the optical depth for three torus sizes. In the two panels at the top, a torus with a constant density distribution is considered, while at the bottom a model with a density gradient is shown (β =-0.5 and γ = 6.0). A type 2 line of sight (Ψ = 90°) is considered in the plots on the left; here, we see that the strongest dependence is on the optical depth rather than the torus dimensions. In the panels on the right, the type 1 view (Ψ = 0°) is shown. The variation of the $S_{9.7}$ parameter is smoother in this case and the most extreme variations are encountered in models with smaller sizes. Models with the density peaking in the innermost regions show a general smaller variation.

The strongest dependence of the silicate emission for type 2 viewing angles is on the optical depth, while the torus size plays a secondary role that becomes more important when a type 1 viewpoint is assumed. In the latter case, the variations are much smoother and smaller torus sizes appear to be more sensitive to changes in optical depth. Hence, assuming a density profile that decreases towards the outer zones makes the interval of $S_{9.7}$ values more narrow with respect to a constant density profile, both in the type 2 and in the type 1 solutions. This is likely due to the fact that the silicate feature in such models is more nested in high optical depth zones, and its presence is attenuated.

Models in which the silicate feature is absent or even measured in absorption for a polar (type 1) view are obtained with high values of the equatorial optical depth [τ (9.7) around 10], smaller outer-to-inner radius ratio and γ = 0. The amount of absorption increases as the exponent β decreases, while positive values yield an almost featureless spectrum. Models with decreasing density at increasing angular distance from the equatorial plane always display the silicate feature in emission, as the hotter innermost regions where the silicate feature is stronger are less extinguished when the torus is seen face-on. The intensity of the silicate emission feature predicted by our model — thanks to the detailed description of the inner torus boundary where the feature is mainly produced — is moderate, and almost absent for τ (9.7) > 1 (see Fig. 9, bottom-right panel).

3.3 Scaling properties of dust emission

Some considerations must be made in order to enable the derivation of various physical quantities for each source from the comparison of the model expectation with the observational data.

All models are computed assuming a luminosity of the primary power source of L^{AGN} = 10⁴⁶ erg s⁻¹. Both the intensity of dust emission and the torus sizes are strongly related to this value, as clearly indicated by equation (1) about the relationship between the minimum radius and

the AGN luminosity. The problem is that of finding how the solutions of the radiative transfer equation depend on the primary power source luminosity and on the size of the emitting region, and how we can scale the spectral solutions from the assumed $L^{AGN} = 10^{46}$ erg s⁻¹ to the value required by the target source.

Rowan–Robinson (1980) notes that the radiative transfer problem has scaling properties that allow a reduction of the number of independent input parameters. These properties were first derived for spherical–shell geometries, but Ivezic & Elitzur (1997) have shown that they are a general property of dust emission in any arbitrary geometry. They have shown in particular that the main pivotal parameter in the dust emission modelling is the overall optical depth. So, as long as the optical depth remains the same, the size of the system can be scaled up or down arbitrarily, without affecting the radiative transfer solution. Obviously, the scale size of the torus distribution determines the value of the dust mass.

Then, assuming a given value for the equatorial optical depth, if we change the source luminosity and size, we have the following scaling relations:

$$\tau \propto \rho R \Rightarrow \rho \propto R^{-1} \Rightarrow \frac{M}{R^3} \propto R^{-1} \Rightarrow M \propto R^2,$$
(14)

where R is the torus radius and M is the total dust mass. However, the torus luminosity is proportional to the grain number density and the grain emissivity e, that is $L \propto \rho e/m \propto M$, where m is the average grain mass. Altogether, total dust mass and torus luminosity scale in the same way, like the square of the linear size.

The mass of dust for a geometrical configuration of the torus is simply calculated as the sum of the mass of all the grains contained in each volume element, summed over all the elements of the grid. The mass of a dust grain is calculated from the typical density of the corresponding grain species, by means of

$$m_i = \frac{4}{3}\pi a_i^3 \rho \tag{15}$$

where the *i* index is meant to represent grains with given size a_i and ρ is the mass density of the species, which was assumed to be 2.26 and 3.50 gr cm⁻³ for graphite and silicate, respectively (see, for example, Weingartner & Draine 2001).

To summarize, the parameters of the torus model include the torus opening angle Θ , the ratio $R_{\text{max}}/R_{\text{min}}$ of the outer-to-inner radii, the coefficients β and γ that enter the density function, and the equatorial optical depth measured at 9.7 μ m. Other parameters, such as for example those describing the distribution function for the sizes of dust grains or their maximum and minimum values, were kept constant in order to avoid further complicating the problem.

A final quantity to consider is the torus viewing angle Ψ . Apart from specific cases, we henceforth assume that it is either Ψ = 0° for a polar view needed to represent type 1 AGNs, or Ψ = 90° for an equatorial view needed for type 2 AGNs.

4 Modelling the Spectral Energy Distribution of Active Galactic Nuclei

In this section we exploit our AGN IR model to study the observed broad-band SEDs of a variety of mostly nearby objects, known to host active nuclei, selected from the NASA/IPAC Extragalactic Database (NED). We confine the study to sources with numerous (at least 10 independent) available photometric data points in order to ensure a good sampling of their SEDs.

A particularly interesting class of active galaxies are the ultraluminous and hyperluminous infrared galaxies (ULIRGs and HyLIRGs, respectively). The studies of ULIRGs by IRAS and later by the *Infrared Space Observatory (ISO)* often revealed the simultaneous presence of starburst and significant AGN dust components, whose respective contributions range from a small fraction up to the totality of the IR SED (e.g. Genzel et al. 1998; Verma et al. 2002; Berta et al. 2003; Prouton et al. 2004). The IR emission of a starburst typically peaks at wavelengths in the range between \sim 50 and 100 μ m (see, for example, Rowan-Robinson et al. 1984; Soifer et al. 1984), while the peak of AGN emission occurs at shorter wavelengths, somewhere between 3 and 40 μ m. Hence, given the fact that AGN and starburst phenomena often occur concomitantly, and that in nearby AGNs the host galaxy component can make an important contribution to the optical and near-IR spectrum, all three components have been included in our spectral modelling. For the cold dust component, the major contributor to the emission at wavelengths longer than \sim 50 μ m, we chose to use starburst templates (see, for example, Farrah et al. 2003). More precisely, M82 represents a typical starburst IR emission while Arp 220 is adopted as representative of a very extinguished starburst. Additionally, NGC 1482, 4102, 5253 and 7714 are used in order to widen the choice of spectral shapes. The main differences between these templates are the intensity of the polycyclic aromatic

hydrocarbon (PAH) features (between ~ 6 and $\sim 15~\mu m$), the depth of the silicate feature at 9.7 μm and the width, intensity and peak wavelength of the IR bump.

A more exhaustive approach would require us to provide also a physical description of the starburst component (e.g. Efstathiou & Siebenmorgen 2005), which however is far beyond the scope of this work. Our simplified approach of using instead observational templates of local starbursts is in line with the current work aimed at modelling the AGN dusty tori and deriving values for the best-fitting parameters from comparison with the data. As explained below, starburst templates are added only when a torus model fails to provide an acceptable description of the observational SED. Concerning the starburst contribution, it is mainly determined by the far-IR data points, predominantly from *IRAS* 60- and 100- μ m measurements, which are prone to considerable uncertainties. For this component we limit our analysis to just an inference of the bolometric IR luminosity. Finally, the stellar component, when needed, is modelled using optical model spectra of ULIRGs in the wavelength range from 0.3 to ~5 μ m, as discussed by Berta et al. (2003) and Fritz et al. (in preparation). Note that we have left free the relative normalization of this optical/near-IR component and the far-IR spectrum of the host galaxy, given the extremely complex physical relation of the two.

4.1 'Prototypical' sources

In order to demonstrate the accuracy and reliability of our spectral modelling, we have studied in some detail the observed SEDs and IR spectra of three well-known nearby objects. One of the three objects, Mrk 231, was chosen because it represents a type 1 AGN-dominated ULIRG, while NGC 1068 was chosen as a prototype type 2 AGN-dominated source. The Circinus galaxy was finally considered as a composite object. All three are very well studied, given their proximity and brightness.

Spectroscopic data in the mid-IR from the *ISO* Short Wavelength Spectrometer (SWS) were available for the three sources, imposing strong constraints on the torus characteristics. For this reason, we built other dedicated models with slightly different characteristics with respect to our reference grid (see Section 3.1), to try to fit both the observed photometry and the mid-IR spectrum.

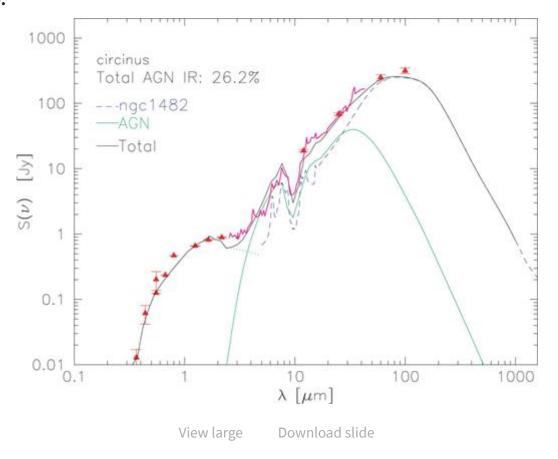

4.1.1 Circinus galaxy

This very nearby (\sim 4 Mpc) source displays characteristics typical of a Seyfert 2 object, such as for example the very intense forbidden optical lines (Oliva et al. 1994) and a broad component of $H\alpha$ emission (Oliva et al. 1998). Moreover, indications of current star

formation activity close to the central region of this spiral galaxy come from near-IR observations (Maiolino et al. 1998) and from the extended morphology of the $H\alpha$ emission (Elmouttie et al. 1998).

The photometric data points available for this source from the optical to the far-IR and the ISO SWS spectrum (2.5–45 μ m; Moorwood et al. 1996; see Fig. 10) strongly constrain the AGN contribution. A large value for the equatorial optical depth [τ (9.7) = 8.0, corresponding to A_V ~ 170 mag] is required in order to depress dust emission between 2 and 10 μ m to match the observed spectrum, and a small value for the torus size (internal and external boundaries of 0.2 and 12 pc, with an aperture angle of 140°) is indicated to reproduce the longer wavelength part of the spectrum. The estimated mass of torus dust is ~380 M_{\odot} , a low value deriving from our small best-fitting torus size.

Figure 10.

The observed SED of the Circinus galaxy (red triangles) including the 2.5–45 μ m /SO SWS spectrum (thick cyan continuous line). The emission has been modelled using the NGC 1482 IR template spectrum (dashed line) plus a highly obscured AGN torus (thin line). The torus has an optical depth $\tau(9.7)$ = 8.0, an aperture angle of 140° and a outer-to-inner radii ratio of 60, and an equatorial view. The bolometric AGN luminosity turns out to be ~1.78 × 10⁴⁴ erg s⁻¹. The density profile of dust follows a power-law radial profile with index β =–1 and γ = 6.0. The integrated stellar emission component was taken from the optical spectrum of IRAS 19254–7245 (Berta et al. 2003; Fritz et al., in preparation).

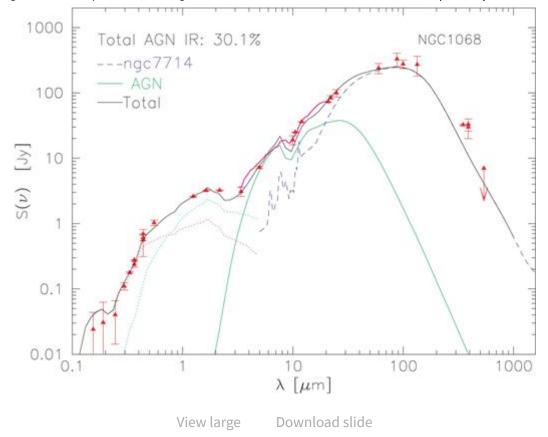

Our torus model component has a flared disc geometry and its main features are quite similar to those suggested by Ruiz et al. (2001): small torus size (the parameter $h/R_{\rm max}$, where h is the vertical size, is ~0.98 for this model) and a high visual extinction. The torus sizes of our solution are fairly consistent with their results. The most important difference concerns the relative starburst—AGN IR contribution: Ruiz et al. (2001) find this ratio to be close to unity, while Moorwood et al. (1996) estimate the ~90 per cent of the total IR luminosity to be ascribed to the AGN component. Our best-fitting value for the AGN contribution is ~30 per cent, much closer to that proposed by Rowan–Robinson & Crawford (1989). Differences in the results might be due to aperture correction effects, because the AGN emission is concentrated in the inner galaxy bulge, while the starburst component is more extended (Maiolino et al. 1998).

4.1.2 NGC 1068

NGC 1068 is a very well-studied prototype Seyfert 2 galaxy and the first against which the unified AGN model was tested (see, for example, Antonucci 1984; Antonucci & Miller 1985). Among others, studies of the putative dusty torus in this source included the IR polarized imaging by Young et al. (1996), the modelling by Efstathiou, Hough & Young (1995) and recent mid-IR interferometric observations by Jaffe et al. (2004) spatially resolving the dusty torus surrounding the active nucleus.

The torus model that better fits the data (see Fig. 11) is one with an outer-to-inner radial ratio of 20, which, rescaled to fit the observed data points, gives a value of about 17.4 pc for the external radius for a luminosity of ~3.9 × 10^{45} erg s⁻¹ of the central source. An optical depth of $\tau(9.7)$ = 8.0 along the equatorial plane, together with a non-constant density profile (β and γ parameters for the density law are -1.0 and 6.0, respectively), yield a silicate feature which is only slightly in absorption, as seen both in the observed SED and in the *ISO* spectrum. The derived optical extinction for such a configuration of the torus is A_V ~ 170, corresponding to a hydrogen column density of 6.98×10^{23} cm⁻² and a total mass of dust of 1.26×10^3 M $_{\odot}$.

Figure 11.

The SED of the Seyfert 2 galaxy NGC 1068, including the *ISO* combined LWS+SWS spectrum (thick magenta line) taken from Genzel & Cesarsky (2000). The model includes the contribution of the IR template of the starburst NGC 7714. The assumed stellar spectrum is obtained as a composition of two models of the ULIRG IRAS 20551–4250 (Fritz et al., in preparation). The torus model has an aperture angle of 160°, an outer-to-inner radii ratio of 20 and a distribution of the dust density varying both in the radial and in the altitude coordinates (β = -1.0 and γ = 6.0), with a value of the optical depth at 9.7 μ m of 8. The total luminosity is 3.9 × 10⁴⁵ erg s⁻¹ and the outer radius ~16.4 pc.

The colder component of dust emission is well reproduced by adding the contribution of the IR template of the starburst galaxy NGC 1482, contributing some 70 per cent of the total IR luminosity. Our results on the AGN torus characteristics are in overall good agreement with previous studies, but indicate a larger torus than that inferred by the interferometric studies of Jaffe et al. (2004), who reveal the presence of dust at 320 K in a structure of 3.4 pc in diameter. Anyway, in the model adopted to reproduce NGC 1068 emission in the mid-IR, the dust reaches such a temperature within a radius of ~8 pc. Considering that the density law in this particular case takes the form

$$\rho(r,\theta) = \alpha r^{-1} e^{-6|\cos(\theta)|}$$
(16)

https://academic.oup.com/mnras/article/366/3/767/992662

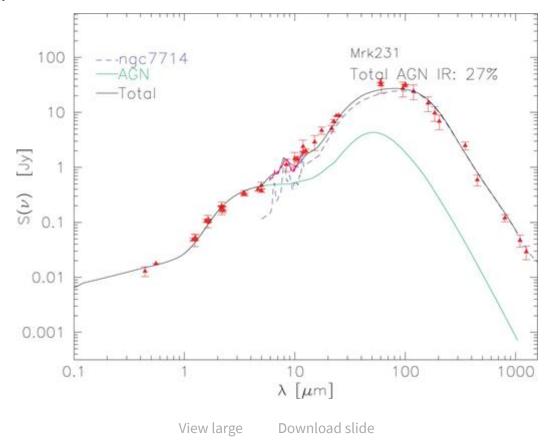

we can easily see that the dust density drops in such a way that at 8 pc it is ~ five times lower than that at ~1.7 pc (the radius reported by Jaffe et al. 2004). Our findings are therefore in marginal agreement with the observations.

4.1.3 Mrk 231

This object is one of the most luminous ULIRGs in the local Universe (Soifer et al. 1984), and also one of the most studied at all wavelengths. Both *ROSAT* and *ASCA* observations found clear evidence of starburst activity combined to that of the AGN (Imanishi & Ueno 1999; Turner 1999). The analysis based on *BeppoSAX* and *XMM-Newton* performed by Braito et al. (2004) indicates the presence of a very thick screen with a hydrogen column density of $\sim 2 \times 10^{24}$ cm⁻² covering the primary X-ray emission.

The torus model is very strictly constrained by the observational data in the 1–5 μ m interval. To reproduce the observed optical-to-IR SED (shown in Fig. 12) we need a direct view of the central power source. The observed SED requires an additional contribution by colder dust at $\lambda > 10~\mu$ m, which we reproduce using the NGC 5253 IR SED.

Figure 12.

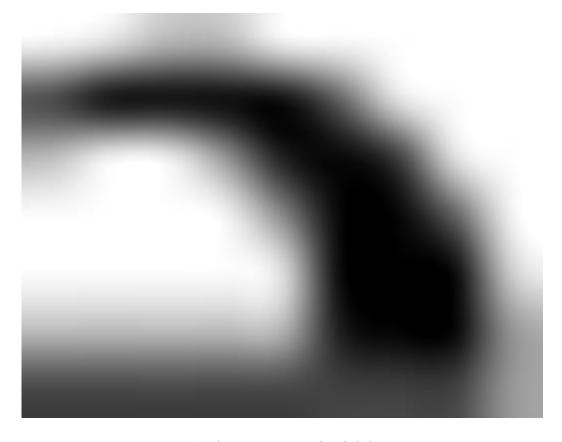

IR SED and spectrum of Mrk 231 versus model fit. To the far-IR part of the SED, the spectral template of NGC 5253 has been added. This type 1 AGN has a torus with optical depth of 10, outer radius of 300 $\times R_{min}$ with

 R_{min} = 0.69 pc and total torus aperture angle of 140°. The line-of-sight angle with respect to the equatorial plane of the torus is Ψ = 25°, hence grazing the upper torus edge.

The torus model has $\tau(9.7) \approx 10.0$ (corresponding to $A_V \approx 210$) and a mass of dust confined in the molecular torus of about $2.7 \times 10^6 \,\mathrm{M_\odot}$, $R_{\mathrm{max}}/R_{\mathrm{min}} = 300$ and the torus aperture angle $\Theta = 140^\circ$. Such a high value for the optical depth implies a hydrogen column density of $\sim 9 \times 10^{23} \,\mathrm{cm}^{-2}$, along the equatorial plane of the torus. The model AGN bolometric luminosity is $2.8 \times 10^{45} \,\mathrm{erg \, s^{-1}}$, corresponding to an outer radius of $\sim 200 \,\mathrm{pc}$.

Our fit (whose parameters are summarized in Table 2) implies an AGN contribution to the IR flux of about 27 per cent, two-thirds of the emission being attributed to the host galaxy. This is consistent with the results by Braito et al. (2004), who found the starburst luminosity to be significantly higher than that of the AGN from a comparison of the X-ray and the bolometric flux and assuming a standard type 1 AGN emission.

Table 2.

View large Download slide

Best-fitting physical parameters of the torus model for all type 1 AGNs. In order, the columns give the object name, redshift, AGN luminosity, inner and outer boundary radii, the full-opening angle of the torus, the radial and angular density dependency, the optical depth at 9.7 μ m, the extinction A_V , the hydrogen column density

 $N_{\rm H}$, the mass of dust and the percentage contribution of the AGN. The latter is computed in the range 5–1000 μ m. The viewing angle Ψ , measured with respect to the z-axis, is in general taken to be 0°, because the models show in general very little dependence on this parameter for type 1 AGNs.

4.2 Further applications

In this section we study the observed broad-band SEDs of a sample of 40 type 1 Seyfert galaxies and quasars and 15 type 2 Seyferts, following the same procedure as in the previous section but making use of our standard grid of models (see Section 3.1). The aim is to obtain information about physical properties of the circumnuclear dust distributions in a sample of local AGNs, as well as on the relative contribution of the host galaxy.

In this exercise, we have taken particular care in selecting photometric measurements within homogeneous apertures, as much as possible. An example is given by our fit of the type 1 AGN NGC 7469 (Fig. 14), for which photometric data with an aperture including only the very central regions are used to constrain the intensity of the AGN component, while the total intensity fluxes include also the host galaxy contribution.

Figure 14.

Comparison of our best-fitting models with observational data for type 1 AGNs. The meanings of the symbols and lines are the same as for Fig. 13.

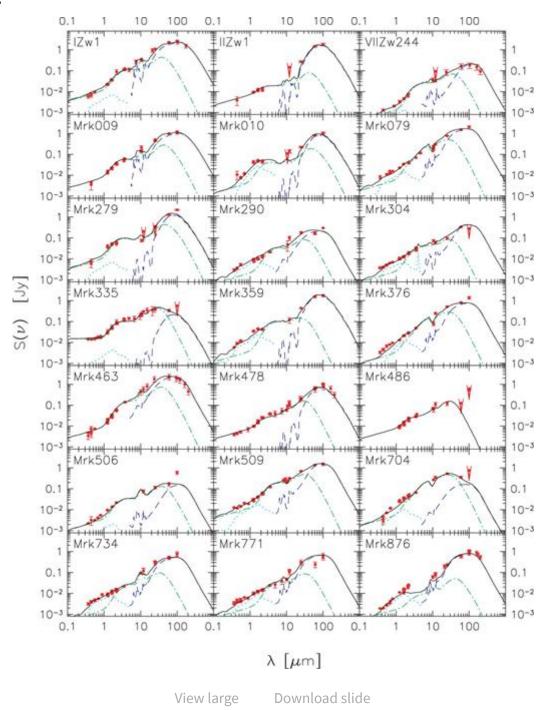

4.2.1 Type 1 active galactic nuclei

A total of 40 type 1 AGNs and quasars, with a good coverage of photometric data points, have been fitted with a combination of stellar, IR starburst and AGN emissions. The objects were chosen from various AGN samples with the only requirement to have a sufficient number of observational data points. Our first attempt was to reproduce the whole optical—IR observed SEDs with a pure AGN emission, trying all models in the grid and assessing their merit with

the χ^2 test. For those objects with unacceptably large χ^2 and obvious far-IR excess, we added starburst and normal galaxy components in the far-IR and optical, respectively.

In all cases the combination of the three emission components reproduced well all the observed SEDs. Figs 13 and 14 show the observed (red triangles) and model (black solid line) SEDs. The figures also report the various components of the model: the IR starburst and AGN contributions as blue dashed and green solid lines, respectively, while the stellar emission is shown as dotted lines.

Figure 13.

Comparison of our best-fitting models with observational data for the type 1 AGNs. Red triangles are the observed data points; the solid black line is the total model SED; the green line is the AGN emission; the blue dashed line denotes the starburst emission; the stellar emission by the host galaxy is shown as dashed lines.

Table 2 summarizes the physical parameters derived for the 41 type 1 AGNs under investigation (including Mrk 231). In order, the columns give the object name, the redshift z, the luminosity of the central power source, the inner and outer torus radii, the full-opening angle of the torus, the radial and angular dust density dependences (parameters β and γ , respectively), the optical depth at 9.7 μ m, the extinction A_V , the hydrogen column density N_H , the mass of dust and the percentage contribution of the AGN to the IR bolometric emission. Note that τ (9.7), A_V and N_H are measured between the inner and outer radii in the torus equatorial plane.

For the majority of the objects (27 out of 40), the contribution of the AGN torus to the total IR emission is larger than 50 per cent. The SEDs of five objects in particular (Mrk 486, IRAS 13349, IRAS 16347, PG1411+442 and PG2112+059) can be entirely reproduced using a pure AGN model, and fitting of their observed SEDs does not require significant cold dust emission.

As for the short-wavelength optical—UV part of the spectrum, there is a remarkable complementarity of the spectral shapes for the AGN and host galaxy: the local minima of one component correspond to the maxima of the other, including the 9.7- μ m emission/absorption. This coincidental fact allows us to assess with some precision the contribution by the host galaxies to optical spectrum. Quite often in these moderate luminosity Seyfert 1 galaxies the latter appears to be important (20 cases out of 40).

Our model solutions for the type 1 objects in this sample tend to favour dust tori in which the density has a radial gradient: 32 of the 40 sample sources require a power-law density profile decreasing with radius (i.e. β =-0.5 or β =-1.0), and six of them also favour an angular dependence (γ = 6.0).

Typical torus sizes are R_{max} < 100 pc. Only for nine objects is an outer radius barely above 100 pc indicated, with the exception of the highest redshift one, IRAS 16347+7037, which has a very luminous central source ($\sim 8 \times 10^{46} \, \text{erg s}^{-1}$) and whose external radius is found to be around 1 kpc. As for the torus geometry, it is remarkable that the majority of our sample sources are well fitted by a high total aperture angle (Θ = 140°), implying a high dust covering factor.

For the large majority of cases, the values of the mass of dust range from a few tens to a few tens of thousands solar masses, orders of magnitudes lower than the typical masses of

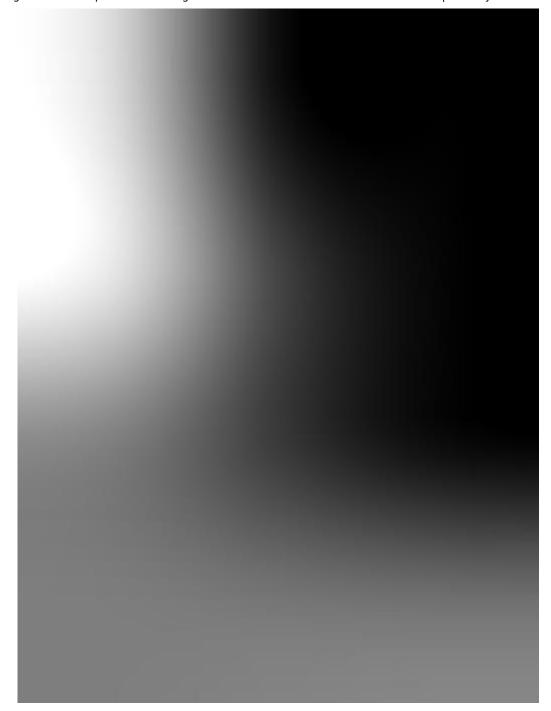

supermassive black holes. A striking exception is again the mass of dust computed for IRAS 16347+7037 found to reach $\sim 10^7 \, \mathrm{M}_\odot$.

Most important, the best-fitting values of the optical depth at 9.7 μm were found to be larger than 1 for almost all the objects, corresponding to visual extinction values larger than 22 mag and hydrogen column densities in the torus that must exceed ~10²³ cm⁻².

4.2.2 Type 2 active galactic nuclei

The same fitting procedure has been used to analyse the observed broad-band SEDs of a small sample of 15 type 2 AGNs. Table 3 summarizes the main best-fitting parameters (including those for Circinus and NGC 1068). The results of our SED modelling (shown in Fig. 15) differ in some aspects from those for type 1 objects.

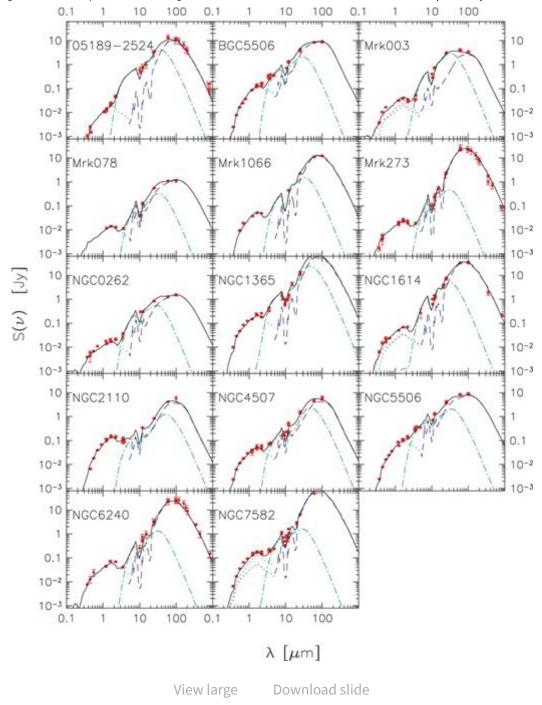

Table 3.

Summary of the main features of the torus model used to reproduce the SEDs of the 17 type 2 objects (including Circinus and NGC 1068). β and γ are the parameters entering the density law, Θ is the full-opening angle of the torus, $\tau(9.7)$, N_H and A_V refer to the equatorial plane of the torus.

Figure 15.

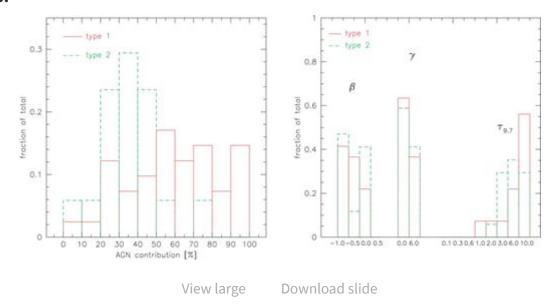

Spectral models for type 2 AGNs. The colour and line coding is the same as in Figs 13 and 14.

Again, all observed SEDs can be very well reproduced by combining stellar, starburst and AGN emission. Note that, in this case, the optical and near–IR emission is entirely due to the host galaxy's stellar contribution, because the AGN emission is totally suppressed at wavelengths shorter than $2-3~\mu m$. None of the type 2 objects can be reproduced with torus emission alone: they all require a substantial starburst component. An Arp 220 starburst template better reproduced the far–IR data in eight out of 15 cases.

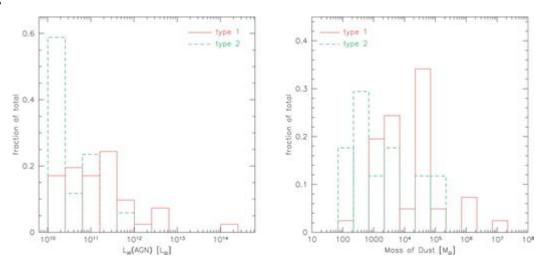

As shown in the left panel of Fig. 16, summarizing a comparison of our best-fitting parameters for the two AGN populations, the average AGN contribution to the bolometric IR luminosity is lower than that estimated for the type 1 objects. We should caution, however, that the two subsamples are distributed quite differently in distance: the redshifts for the type 1 objects (appearing in the same Fig. 16) are typically higher than for the type 2 objects, because of their easier spectroscopic identification. This bias obviously affects the bolometric AGN luminosity and dust torus mass (Fig. 17), while it is unclear at this stage how much it might influence the estimate of the AGN fractional contribution.

Figure 16.

Left panel: fractional contribution of the AGN component to the IR bolometric (5–1000 μ m) luminosity versus the redshift, for type 1 AGNs (red solid line) and type 2 AGNs (green dashed line). Right panel: summary of the main characteristics of the torus best-fitting parametric solutions, with a comparison of type 1 (red continuous line) and type 2 (green dashed line) sources.

Figure 17.

Download slide

The distribution of the values of dust masses for type 1 and type 2 sources does not seem to highlight deep differences between the two classes, while the distribution of the IR luminosity that is ascribed to the AGN component is more peaked towards the low-luminosity part of the plot. This effect is due to the fact that the starburst component is more important in type 2 sources.

It is remarkable that, in spite of this bias, the distributions of the main physical and geometrical parameters for the two classes of AGNs are fairly consistent, in particular the optical depth, with a median value of $\tau(9.7)$ of 6.0 for the type 2 sample, while it is 10.0 for the type 1 sample. In any case, the results should be viewed with caution because of the inhomogeneity, incompleteness and random character of our sample.

5 Discussion and Conclusions

In this paper we have described an improved model for the emission of dusty tori around AGNs, including features already occasionally discussed in the literature, and paying particular attention to an accurate computation of the radiative transfer solution. The chosen torus geometry is simple but realistic, a flared torus defined by its inner and outer radii and the total opening angle. We adopt the dust grain distribution of Mathis et al. (1977), with the density depending on the torus radial coordinate and polar angle. The optical depth is computed in great detail, taking into account the different sublimation temperatures for silicate and graphite grains.

The fact that grains with different sizes can have different sublimation temperatures may imply a significant complication, especially in the inner parts of the torus where the temperature of some dust grains can reach and exceed the sublimation limit. While this model accounts for the differences between graphite and silicate grains, we assume the sublimation temperature to be independent of the grain size. This follows Efstathiou & Rowan–Robinson (1994), who have shown that this effect is not of much importance especially for high densities and optical depths.

Our model is able to reproduce with remarkable accuracy the observed broad-band SEDs of a variety of AGNs, for which large numbers of photometric measurements were available in the literature. For three well-known nearby active galaxies (Circinus, NGC 1068 and Mrk 231), the *ISO* mid-IR spectrum was also available, in which cases both the torus model and the starburst contributions were strongly constrained.

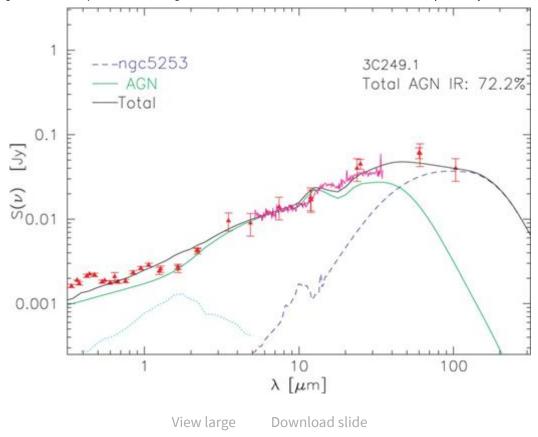

5.1 Spectral fitting of type 1 active galactic nuclei

A starburst component is usually required in order to fit the observed SED longwards of 50 μ m, as in most cases a pure AGN component is unable to reproduce the observed width of the IR bump. From the objects of our sample, only four type 1 sources can be fitted by a pure AGN emission in the far-IR. The torus emission is in general predominant for such objects, while the starburst prevails in type 2 sources (see Fig. 16, left panel).

In this work we pay particular attention to the behaviour of the 9.7- μ m silicate feature, which in many previous publications was found to challenge the unified model (especially for type 1 objects). The problem was the prominence of the feature in absorption for type 2 AGNs and its absence in type 1 objects, as viewed pole-on. This feature arises from dust situated in the innermost regions of the torus, as seen in Fig. 3, where the temperature is close to the sublimation limit. Moving far away from the centre, the feature becomes gradually fainter until it eventually turns into absorption if the optical depth is high enough. Our current results show that a combination of high optical depth, moderate torus radius, an either constant density profile or one radially increasing toward the centre, and a proper consideration of the lower sublimation temperature of silicate grains reduces the silicate emission or even turns it into slight absorption. Under these assumptions, a standard composition of the mixture of dust turns out to be entirely compatible with low or no silicate emission in our model. The addition of a significant starburst contribution with the silicate feature in absorption tends to further decrease the prominence of the 9.7- μ m feature in type 1 AGNs.

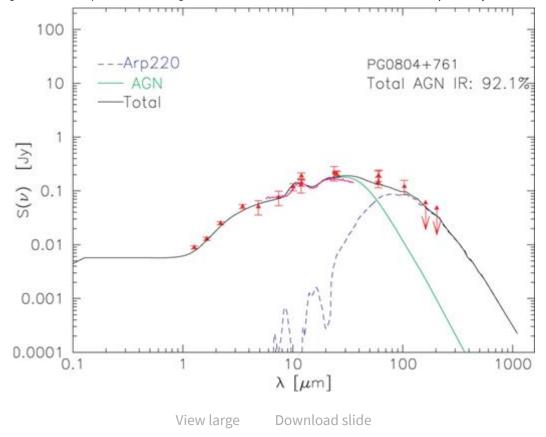

Recent observations with the *Spitzer* IR space telescope have revealed, for the first time, evidence for the silicate feature in moderate emission in a few type 1 AGNs (Siebenmorgen et al. 2005; Hao et al. 2005), with values of the $S_{9.7}$ parameter close to unity. Indeed, the latter can be achieved with several combinations of our torus parameters (see Fig. 9). We present in Figs 18 and 19 a detailed comparison of IR *Spitzer* spectra, together with SED data in the optical and far-IR, of two type 1 quasars (3C249.1 and PG0804+761) with evidence for the 9.7- μ m feature in emission. We see that our model provides an excellent fit of the spectral shape and broad-band data for the latter source. As for the former, the spectrum is also well reproduced, except for a slight shift in wavelength probably due to a locally different grain mixture (Siebenmorgen et al. 2005). In conclusion, we find no need for particular geometries, such as a tapered disc, or for modified distributions of the silicate grains (clumpy tori) in order to suppress the silicate feature in type 1 sources.

Figure 18.

Model fit to the observed SED and the IR *Spitzer* spectrum (observed by Siebenmorgen et al. 2005) between 5 and 30 μ m of the luminous quasi-stellar object 3C249.1. The 9.7- μ m silicate feature is clearly seen in emission with an intensity which is very close to that of our model. The discrepancy in the wavelength of the observed peak is likely due to a different chemical composition of the silicate grain (Siebenmorgen et al. 2005; Hao et al. 2005). A non-constant density profile with γ = 6 and β =-1.0 and a torus aperture angle of 100° are used, while the external radius is ~35 pc.

Figure 19.

Comparison of the *Spitzer* spectrum (Hao et al. 2005) and other SED data points with our model expectation for the type 1 AGN PG0804+0761. The model is similar to that fitting 3C249.1 (see Fig. 18 and parameters in Table 2). In this case, our fit to the silicate peak is very good.

5.2 Torus geometry and the unified model

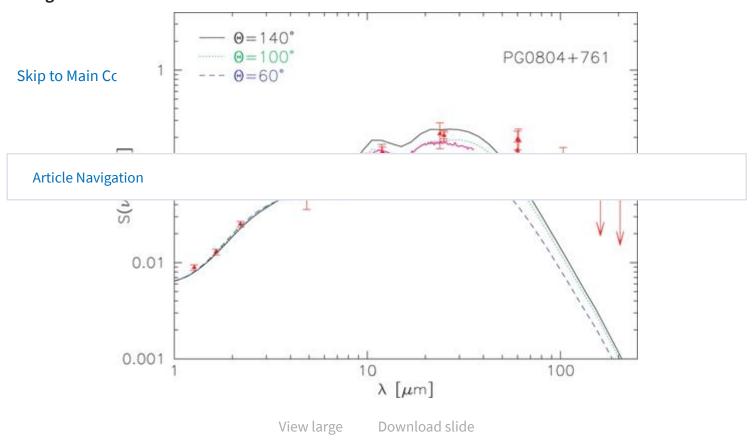

We now discuss results related to the unified scheme. Fig. 16 (right panel) illustrates the best-fitting values of the parameters reproducing the observed SED of type 1 and type 2 AGNs. Non-constant dust density profiles, in particular a density decreasing with the distance from the centre, are clearly favoured. Furthermore, high values for the equatorial optical depths are required in almost all the sources, particularly to suppress the 9.7- μm emission. Interestingly, in agreement with the predictions of the unified scheme and despite the different average distances for the type 1 and type 2 samples, the distributions of the geometrical and physical torus parameters do not show significant variation between the two populations.

Also the distribution of values for the mass of dust in the torus and the luminosity of the primary power source presented in Fig. 17 do not show dramatic differences between type 1 and type 2. The slight tendency of type 1 objects to host more luminous AGNs and more massive tori may be explained with the Malmquist bias introduced by the different average distances. More problematic is, instead, the interpretation of the higher fraction of the AGN contribution in type 1 sources, seen in Fig. 16 (left panel). It is unclear whether this is still a

result of a distance-induced bias, or if it is reflecting an intrinsic differentiation of the two populations.

Obviously, not only the silicate feature, but more in general the observed mid-IR spectral shape can effectively constrain the intrinsic properties of the circumnuclear dust distribution. An illustration of this is given in Fig. 20, showing how the spectrum changes by reducing the torus full-opening angle Θ from 140° to 100° and 60°: the reduced amount of cold dust close to R_{max} for the 60° case makes the spectrum very flat in flux density units from ~3 to ~50 μ m, whereas a much steeper one is produced by our more standard value of Θ = 140°.

Comparison of predicted spectra for a torus aperture angle of 140° (continuous line), 100° (dotted line) and 60° (dashed line), for a model with the same characteristics as that used in Fig. 19. Data points are as discussed in the caption of Fig. 19.

A further important implication of our work is that, even accounting for important starburst contributions to the longer-wavelength far-IR part, our code was essentially unable to obtain good spectral fits to both AGN classes by assuming relatively flat tori with low values of the opening angle Θ = 60°. Instead, roughly half of the type 1 AGNs and 70 per cent of the type 2 AGNs require almost cylindrical tori with Θ = 140°. For these, the corresponding

covering factor is ~90 per cent, while the remaining sources are better fit with Θ = 100° models, corresponding to ~75 per cent covering factor.

Altogether the average covering factor for our local sample is close to 80–85 per cent: four to five obscured AGNs are then to be expected on average for each type 1 unobscured object (we predict very thick circumnuclear material, $A_V > 100$). Because local and high–z AGN samples, including those selected in the IR (e.g. Rush, Malkan & Spinoglio 1993; La Franca et al. 2004) or in radio (Lawrence 1991; see also Maiolino & Rieke 1995), do not typically reveal such a high incidence of obscured objects, it remains that a large number of completely obscured AGNs are to be expected, indistinguishable from normal galaxies if observed in the optical/near–IR or soft X–rays. This appears consistent with the results of Franceschini et al. (2005) from a deep combined *Spitzer/Chandra* survey. As discussed there (see also Fabian 2003; Maiolino et al. 2003; Gandhi et al. 2004), an important fraction of the obscured quasars and AGNs may escape identification, even with a good coverage of the mid–IR and far–IR spectrum, as given by the *Spitzer* data, or deep hard X–ray data.

5.3 Model degeneracies

Article Navigation

limited spectral coverage, especially in the mid–IR. As already shown for the three prototype objects analysed in Sections 4.1.1, 4.1.2 and 4.1.3, the mid–IR spectrum turns out to be fundamental constraining the model parameters of AGN dust tori. The shape of the mid–IR (1–12 μm) continuum is ruled by the optical depth and the characteristics of the density law, while the shape of the far–IR SED (20–400 μm) is mainly determined by the torus size and the amount of cold dust.

In order to study the degree of degeneracy of our fits, a detailed case study of the following three objects was performed: PG1411+442, as representative of type 1 objects with no evident starburst contribution; Mrk 1513, as a type 1 source with significant contribution from starburst emission in the IR; and NGC 1614 as a representative of the type 2 sources.

We have compared the observed SEDs for the three sources with all model spectra corresponding to the whole parameter set in Table 1, and then considered the solutions with a reduced χ^2 below χ^2_{best} + 3. The accretion luminosity turned out to be the best constrained quantity, especially in the type 1 sources where the primary continuum emission is observable. The scatter was found to be larger for the type 2 NGC 1614, in which case it varied between ~0.75 × 10⁴⁶ and ~10⁴⁶ erg s⁻¹, the higher values corresponding to model solutions with smaller torus opening angles.

The values of the outer radius were fairly constant for the best-fitting models in NGC 1614, but differed by up to a factor of 3 in the case of PG1411+442 (both $R_{\text{max}}/R_{\text{min}}$ = 30 and 100 gave acceptable fits).

Similar results were obtained for the mass of dust. The most extreme case was again PG1411+442, with a variation by up to a factor of 4, as a consequence of the $R_{\text{max}}/R_{\text{min}}$ variation. However, the parameters of the dust density law (equatorial optical depth and the coefficients β and γ of the density law) were found to only slightly vary among the best fits. The starburst template that better fitted the objects was Arp 220 and was kept fixed as no acceptable fits could be obtained with other templates.

In conclusion, the available data are not so detailed to allow resolution of all degeneracies in the torus parameters, which we may understand if we consider the complexity of the objects under scrutiny and the fact that the torus and starburst emissions overlap smoothly in the far-IR. However, our analysis has shown that significant constraints can be achieved about Skip to Main Content the circumnuclear dust distributions in AGNs.
